| <b>14. ABSTRACT</b><br>This study investigates the morphological control of the melanin-producing fungus <i>Curvularia lunata</i> to support the development of melanized biomaterials for advanced military applications. While researchers seek to dictate morphology using agitation-induced shear stress, the quantitative relationships governing these dynamics remain poorly characterized. <i>C. lunata</i> was cultivated across various agitation speeds (50–250 rpm), flask sizes (250 and 500 mL), and media volumes to further tease out the impact of differences in agitation-induced shear stress. However, efforts to isolate and magnify these mechanical differences revealed that shear stress cannot be separated from the broader physiochemical system. The results demonstrate that while massive differences in agitation drive a distinct hyperbranching response, the dominating influence of agitation-induced shear stress on morphological outcomes is reduced at lower speeds. As agitation becomes less overwhelming, inseparable environmental variables—coupled with the fungus’s own biological responses—predominate. Specifically, these lower-shear environments promoted the secretion of extracellular polysaccharides, driving hyphal aggregation and subsequent anastomosis (hyphal fusion). Ultimately, our findings show that morphological control cannot be reduced to stirring intensity alone; rather, it requires a systemic approach that accounts for both network expansion and network connection mechanisms. |                                    |                                         |                                             |                                                                 |                                |

## List of Figures

---

- Figure 1. Representative images of samples grown at (A) 50, (B) 125, and (C) 250 rpm within 250-mL shake flask taken with a light microscope. Size bars = 50  $\mu\text{m}$ . ..... 3
- Figure 2. Average number of hyphal tips for samples grown in 250-mL shake flask at agitation speeds of 50, 125, and 250 rpm for 15.5 h. Samples grown at 250 rpm exhibit significantly more hyphal tips compared to samples grown at 50 and 125 rpm. Error bars indicate standard error of mean. .... 4
- Figure 3. Average number of hyphal tips for samples grown in 500-mL shake flask at agitation speeds of 50, 75, 100, and 125 rpm for 15.5 h. Samples grown at 125 rpm exhibit significantly more hyphal tips compared to samples grown at 50 and 75 rpm. Error bars indicate standard error of mean. .... 5
- Figure 4. Comparison of average number of hyphal tips between samples of the same speed grown in different sizes of shake flasks. The average number of tips is significantly different between samples grown at 125 rpm in different sizes of flasks, but this is not different for samples grown at 50 rpm, which indicates that 50 rpm is inadequate for evaluating agitation-induced shear stress effects on hyphal branching. 6
- Figure 5. Comparison of the average number of hyphal tips between samples of the same speed grown within the same size of shake flasks containing different volumes of media. The average number of tips is significantly lower between samples grown in 60 mL of media compared to samples grown in 100 mL of media. .... 7
- Figure 6. Samples grown in 60-mL samples within 500-mL shake flask at different speeds. Panel A shows an abundance of extracellular polysaccharides secreted by the hyphae surrounding its perimeter, whereas panel B shows minimal presence of the EPS collecting around the hyphae at a higher speed. .... 8

## 1. Introduction

---

The development of melanized biomaterials is of significant interest to the U.S. Army for potential integration into advanced Warfighter equipment. Melanin, a highly valued natural biopolymer, is prominently found in filamentous fungi—organisms characterized by root-like structures called hyphae that branch to form resilient networks known as mycelia.<sup>1–5</sup> These fungi are widely recognized as formidable biomaterials due to their structural strength and ability to grow rapidly using minimal inputs.<sup>6–10</sup> However, to successfully harness and incorporate these melanized biomaterials into Army applications, precise control over their branching morphology, or appearance, is essential. Currently, mechanisms to reliably dictate these morphological outcomes remain an active area of research.

The expansion of fungal networks is determined by two primary physical behaviors: exploratory growth (apical elongation and lateral branching) and network connection (hyphal aggregation and anastomosis/hyphal fusion).<sup>11–16</sup> Research reports numerous environmental cues largely influence these expansion behaviors, but anastomosis, or the physical fusion of neighboring hyphae to form connected networks known as hyphal fusion, often obscures more mature mycelial networks and complicates research efforts to characterize the impacts of individual environmental variables.<sup>11,13,17,18</sup> This limitation drives most research to focus on controlling space-filling behaviors through the manipulation of growth environments such as changing agitation speeds.<sup>19</sup> Morphological outcomes from these studies are species dependent, demonstrating a need for dedicated characterization of non-model organisms.<sup>20–24</sup>

This study investigates *Curvularia lunata*, a highly melanated fungus of interest, and its morphological response to agitation-induced shear stress. This work was motivated by Dr. Matthew Servinsky's preliminary observations of *C. lunata*'s disparate morphologies under two different extremes of agitation-induced shear stress. To better understand *C. lunata* morphologies for material generation, this work utilizes a novel quantitative characterization between agitation-induced shear stress and hyphal branches in a shaking incubator.

## 2. Methods and Procedures

---

### 2.1 Fungal Strains and Growth Media

---

In all experiments, we used the 42011 wild-type strain of *C. lunata* obtained from the American Type Culture Collection (ATCC, Manassas, Virginia) and grown on Potato Dextrose Agar (PDA) agar plates until confluency.

## **2.2 Preparation of Samples in 250-mL Shake Flask**

---

Conidia from confluent PDA plates of *C. lunata* were harvested using 5 mL of sterile deionized (DI) water and a sterile L-shaped cell spreader. Spore solution was filtered through a 40- $\mu$ m cell strainer (Greiner Biosciences) and diluted to a concentration of 4,000 conidia/mL. The diluted solution was inoculated into 250-mL unbaffled glass volumetric flasks containing 100 mL of yeast peptone dextrose (YPD) liquid media. Inoculated flasks were shaken at a single speed for 15.5 h at 28 °C. The speeds tested were 50, 125, and 250 rpm, and three different bioreplicates were used for each speed.

## **2.3 Preparation of Samples in 500-mL Shake Flask**

---

Conidia from confluent PDA plates of *C. lunata* were harvested using 5 mL of sterile DI water and a sterile L-shaped cell spreader. Spore solution was filtered through a 40- $\mu$ m cell strainer and diluted to a concentration of 4,000 conidia/mL. The diluted solution was inoculated into 500-mL unbaffled glass volumetric flasks containing 100 mL of YPD liquid media. Inoculated flasks were shaken at a single speed for 15.5 h at 28 °C. The speeds tested were 50, 75, 100, and 125 rpm, and three different bioreplicates were used for each speed.

## **2.4 Preparation of Samples in 500-mL Shake Flask in 60 mL of YPD**

---

Conidia from confluent PDA plates of *C. lunata* were harvested using 5 mL of sterile DI water and a sterile L-shaped cell spreader. Spore solution was filtered through a 40- $\mu$ m cell strainer and diluted to a concentration of 4,000 conidia/mL. The diluted solution was inoculated into 500-mL unbaffled glass volumetric flasks containing 60 mL of YPD liquid media. Inoculated flasks were shaken at a single speed for 15.5 h at 28 °C. The speeds tested were 75 and 100 rpm, and three different bioreplicates were used for each speed.

## **2.5 Imaging of Fungal Hyphae**

---

To image hyphae for branching analysis, shake flasks were removed from the incubator after 15.5 h, gently scraped with an autoclaved plastic spatula, swirled to collect all the loose hyphae in the flask, and emptied into 500-mL Nalgene filter units. While gently swirling the Nalgene unit, the liquid is filtered through with a vacuum on low to isolate the hyphae. While the vacuum is off, 10 mL of sterile DI water is added back to the top of the Nalgene unit, gently scraped with a new plastic spatula, swirled again, and emptied into a 50-mL conical tube. After using the number “2” setting to vortex the spore solution in the conical tube for 7 s, a p100

micropipette with a diagonal cut at the second hash mark of the p100 tip was used to aspirate 25  $\mu$ L of spore solution onto a microscope slide. After covering the microscope slide, 40 images—identifying at least 1 hyphae clearly—were taken using an inverted microscope at 10 $\times$  magnification (Mateo FL) under brightfield and contrast lenses.

## 2.6 Analysis of Fungal Hyphae

---

For each bioreplicate, the number of tips for 30 different hyphae analyzed from the images collected were counted and placed on a spreadsheet. The total number of hyphal tips, representing branching, was averaged per condition (agitation speed, volume of shake flask, and volume of media) and graphed along with their respective standard error for comparison.

## 3. Results and Discussion

---

### 3.1 Branching Analysis of 250-mL Shake Flask Samples

---

Previous studies show that fungal branching is a dynamic response to its environment.<sup>25–28</sup> Our original hypothesis, inspired by Dr. Servinsky’s early observations, anticipated that environments with greater agitation-induced shear stress would increase both hyphal collision frequency and local oxygenation—two synergistic factors that change the local environment and are suspected to drive enhanced hyphal branching.<sup>26,29–35</sup> Figure 1 shows samples grown at 50, 125, and 250 rpm. Figure 2 shows samples grown at 250 rpm exhibited a significantly higher average number of hyphal tips ( $P < 0.05$ ) compared to those grown at 50 and 125 rpm. No significant difference was observed between 50 and 125 rpm despite a twofold difference in speed. Although the 250-rpm data demonstrates that doubling the agitation rate can drive a distinct branching response, the lack of variation between the lower speeds exhibiting a similar twofold difference suggests that the current growth environment may obscure the authentic branching morphologies we expected at lower agitation thresholds.

**Figure 1.** Representative images of samples grown at (A) 50, (B) 125, and (C) 250 rpm within 250-mL shake flask taken with a light microscope. Size bars = 50  $\mu$ m.

**Figure 2.** Average number of hyphal tips for samples grown in 250-mL shake flask at agitation speeds of 50, 125, and 250 rpm for 15.5 h. Samples grown at 250 rpm exhibit significantly more hyphal tips compared to samples grown at 50 and 125 rpm. Error bars indicate standard error of mean.

### 3.2 Branching Analysis of 500-mL Shake Flask Samples

To more accurately assess the relationship between agitation-induced shear stress and resulting branching morphologies, we reduced oxygen and nutrient gradients suspected of obscuring differences between agitation speeds in the previous environment by repeating the experiment at 50, 75, 100, and 125 rpm within a larger 500-mL glass, unbaffled shake flask containing 100 mL of media. Figure 3 shows that samples grown at 125 rpm have significantly more hyphal tips compared to samples grown at 50 and 75 rpm. Samples grown at 100 rpm statistically produce an equal amounts of hyphal tips compared to samples grown at 50, 75, and 125 rpm, suggesting that a critical energy threshold—greater than the energy produced at 100 rpm in this environment—is required to significantly alter hyphal branching.<sup>20,36–41</sup> Similar studies report that energy thresholds are governed by shear stress, which is naturally inseparable from other physiochemical variables—mainly including mass transfer rates and fluid dynamics.<sup>41–43</sup> Therefore, altering the agitation speed simultaneously impacts multiple variables within a shake flask, inducing a systemic change across the entire growth environment.

**Figure 3.** Average number of hyphal tips for samples grown in 500-mL shake flask at agitation speeds of 50, 75, 100, and 125 rpm for 15.5 h. Samples grown at 125 rpm exhibit significantly more hyphal tips compared to samples grown at 50 and 75 rpm. Error bars indicate standard error of mean.

Figure 4 illustrates how different environments—one inside a 500-mL shake flask operating at a 20% fill ratio and the other inside a 250-mL shake flask operating at a 40% fill ratio—alter hyphal branching outcomes at 50 and 125 rpm across identical initial conditions. Our data shows samples grown in 500-mL shake flasks at 125 rpm exhibit significantly more hyphal tips than samples grown in 250-mL shake flasks; samples grown at 50 rpm exhibited identical hyphal branching tip averages in both vessels. Flask volume-induced environmental differences affected branching at 125 rpm as predicted but not at 50 rpm, suggesting a low speed created a quasi-static growth environment at 50 rpm that was outside the scope of this study.

**Figure 4.** Comparison of average number of hyphal tips between samples of the same speed grown in different sizes of shake flasks. The average number of tips is significantly different between samples grown at 125 rpm in different sizes of flasks, but this is not different for samples grown at 50 rpm, which indicates that 50 rpm is inadequate for evaluating agitation-induced shear stress effects on hyphal branching.

### 3.3 Branching Analysis of 500-mL Shake Flask Samples in 60 mL of YPD

To better characterize how agitation-induced shear stress impacts branching morphologies, we repeated the previous experiments using 60 mL of media in 500-mL shake flasks at 75 and 100 rpm. We hypothesized the reduced volume of media would further mitigate both oxygen and nutrient gradients suspected of obscuring differences between agitation speeds from previous conditions. We expected this change would magnify differences in hyphal branching between speeds. Figure 5 shows a significant decrease in branching among the samples grown in 60 mL of media compared to the samples grown in 100 mL, but there was no difference in hyphal branching between different speeds grown in the same volume of media.

**Figure 5.** Comparison of the average number of hyphal tips between samples of the same speed grown within the same size of shake flasks containing different volumes of media. The average number of tips is significantly lower between samples grown in 60 mL of media compared to samples grown in 100 mL of media.

The identical branching morphologies consistently observed across different environments within a narrower range of agitation speeds suggest that other variables besides shear stress may significantly influence morphological outcomes. In addition, all shake flasks containing 60 mL exhibited reduced branching compared to their 100 mL counterparts, contradicting previous trends of increased shear stress driving hyperbranching morphologies as observed in Figures 2 and 3. To identify the variables overriding the expected difference in branching from agitation-based shear stress, we examined the hyphal microenvironment. As shown in Figure 6A, we observed an abundance of suspected extracellular polysaccharides (EPS)—primary contributors to the aggregation of hyphae<sup>44–49</sup> and known precursors to anastomosis capable of altering late-stage fungal morphology.<sup>13,18,50–52</sup> The EPS in Figure 6A was visually identified based on its characteristic mucous-like appearance surrounding the hyphae, consistent with morphological descriptions and imaging standards established in literature.<sup>53–57</sup>

**Figure 6.** Samples grown in 60-mL samples within 500-mL shake flask at different speeds. Panel A shows an abundance of extracellular polysaccharides secreted by the hyphae surrounding its perimeter, whereas panel B shows minimal presence of the EPS collecting around the hyphae at a higher speed.

## 4. Conclusions

In the fungal manufacturing industry, specific morphologies are known for driving the bioprocessing of high-value products.<sup>26</sup> A complete understanding of 1) critical process parameters, 2) how these processes can be controlled, and 3) resulting fungal morphologies are required for maximizing the industrial potential of fungi as a living production platform.<sup>26</sup> The same logic should be applied for the successful use of fungi as a living material concerning Army applications. This study investigates a quantitative characterization of the relationship between agitation-induced shear stress—a critical process parameter—and representative branching dynamics in *C. lunata* within nutrient-abundant shake flask environments.

Researchers' current efforts to understand the morphological control of fungi largely consist of species-dependent results accrediting morphology exclusively to agitation rates but overlooking how stirring alters the entire physiochemical system.<sup>11,12,58–60</sup> Our findings demonstrate that massive differences in agitation-induced shear stress drive a hyperbranching response while also indicating the existence of a potential critical energy threshold. Our data shows when agitation intensity decreases towards a critical energy threshold that typically induces hyperbranching responses within an environment, the inseparable variables accompanying agitation and the fungus's own secondary biological responses gain more influence over the organism's final morphology. Specifically, at these lower agitation speeds, we observed a collection of EPS from *C. lunata* that we suspect led to anastomosis (hyphal fusion) based on our data.<sup>13,18,50–57</sup>

Improved control of morphological outcomes requires deeper knowledge of how an entire system responds to input changes such as agitation speed. Further studies of anastomosis, particularly in relation to EPS production within production

vessels, are the recommended next steps to accomplish this. Combining this effort with continued studies of associated parameters, such as nutrient gradients and oxygen transfer rates, will lead to a comprehensive understanding of the relationship between shear stress and morphology necessary for improved material generation and expanded application use.
